Immune Related Genetic Polymorphisms and Schizophrenia Among the Chinese

K. Venkat Chowdari, Ke Xu, Feng Zhang, Cui Ma, Ting Li, Biao Yong Xie, Joel Wood, Massimo Trucco, W-F Tsoi, Nilamani Saha, Willam A. Rudert, and Vishwajit L. Nimgaonkar

ABSTRACT: Genetic association studies were conducted among two independent cohorts of Chinese ethnicity. The samples consisted of cases and unrelated controls, ascertained from Guangzhou, China, and Singapore. The studies were prompted by our earlier report of an association between schizophrenia and HLA DQB1 alleles (HLA DQB1*0602 and HLA DQB1*0303) in the Singapore sample. Polymorphisms of HLA DQB1 and flanking markers on chromosome 6p21.3 were investigated in the first part of the study. A significant negative association with HLA DQB1*0402 was detected in the Guangzhou sample (Odds ratio, OR 0.26, 95% confidence intervals, CI 0.1, 0.6; $p < 0.02$, corrected for multiple comparisons). Additional analysis of the Guangzhou and Singapore samples revealed associations at three other any-

mous markers flanking HLA DQB1. In the second part of the study, three polymorphisms at the Interleukin-1 gene cluster (IL-1, chromosome 2q13-q21) were investigated in both cohorts, since associations with schizophrenia have been reported in another sample. Persuasive evidence for an association at IL-1 was not detected in either sample. Our results suggest a susceptibility locus for schizophrenia in the HLA region among the Chinese, but further clarification is necessary. *Human Immunology* 62, 714-724 (2001). © American Society for Histocompatibility and Immunogenetics, 2001. INTRODUCTION

Several studies have documented differences between patients with schizophrenia and suitably matched controls with respect to immunological measures such as cytokine concentrations or lymphocyte subsets [1-6]. It has also been suggested that a sub-group of patients have increased prevalence of autoimmune diseases as well as antinuclear and anticytoplasmic antibodies [1, 7, 8, 9]. The prevalence of rheumatoid arthritis and type I diabetes mellitus may be reduced among patients with schizophrenia, suggesting shared etiology between schizophre-

nia and these autoimmune conditions [10, 11]. Some of the results could be due to medications, but other groups have also reported increased prevalence of autoimmune diseases among medication free nonschizophrenic relatives of probands [12-16]. Thus an autoimmune pathology for schizophrenia is plausible, though persuasive evidence is unavailable [8, 16-19]. The inconsistencies may have resulted from the variable effects of other nonspecific clinical factors such as stress [20, 21]. More reliable results may be obtained if heritable immunological factors are examined.

Linkage studies form the cornerstone for identifying genes predisposing to human disease. However, genome wide linkage studies have not yielded consistent results for schizophrenia, even though the heritability is estimated at 70% [22]. The variable results may be due, among other reasons, to the presence of several genes of relatively modest effect. Candidate gene association strategies are gaining popularity for gene mapping studies because such genes may be detectable using this ap-

proach [23]. Association studies make no assumptions about the mode of inheritance. For both reasons, they are potentially useful in schizophrenia. The present study describes studies involving immune related genes, for which associations with schizophrenia have previously been reported.

HLA and Schizophrenia

Association studies have focused on the HLA region on chromosome 6p21 for over three decades, but the results have been inconsistent [24–27]. Some of the inconsistencies may have arisen because most early studies examined HLA class I, but not class II markers. The latter are more likely to be associated with autoimmune diseases. The early studies also used serological methods, which are more error prone in comparison with PCR based assays [28].

Several recent PCR based analyses of class II markers among Caucasian and Japanese samples have reported significant associations with alleles of HLA DPB1 or HLA DRB1 [29–32]. Two recent family based studies among Caucasian samples also suggest an association at HLA DRB1 [27, 31]. Even so, several other case-control studies have failed to detect significant associations in the HLA region [26, 33, 34]. Therefore, the question of HLA association with schizophrenia is unresolved.

Over 90% of the HLA studies in schizophrenia have been conducted in Caucasian samples. It is plausible that an association is present among other ethnic groups even if it is not detectable reliably among Caucasians. Such variations have been reported for associations of HLA DQB1 alleles with type I Diabetes Mellitus [35]. Indeed, our prior studies suggest a "negative" association with HLA DQB1*0602 among African-Americans, which could not be detected among Caucasians [26, 35, 36]. In other words, the frequency of HLA DQB1*0602 was significantly reduced among African-American cases compared with control values. However, a spurious association may have occurred among the African-Americans due to known genetic admixture between Caucasian and African genes [37].

To test ethnic differences with regard to the association, an independent Chinese sample from Singapore was investigated. A significant negative association with HLA DQB1*0602 and a significant "positive" association was detected with HLA DQB1*0303 in this sample [38]. This association was also notable because the diagnostic criteria for the Chinese cases (International Classification of Diseases, 10th revision, ICD 10) were different from the African-American sample (DSM-III-R). Thus, the HLA DQB1 association appeared to be robust to diagnostic variations. Furthermore, the molecular genetic techniques employed in the studies were different,

arguing against a systematic laboratory error. Taken together, these studies support an association in the HLA region among the Chinese.

Nevertheless, other considerations remain. First, the controls for the Chinese samples were unrelated adults who had been selected during a pre-employment checkup. Significant bias may be introduced by the screening process [39]. Second, the presence of hitherto unknown HLA DQB1 alleles could lead to genotyping errors. Both these possibilities were examined in the present study. DNA polymorphisms at HLA DQB1 and flanking loci were initially examined among independently ascertained cases and adult controls from Guangzhou, China. The flanking markers included short tandem repeat polymorphisms (STRPs). We reasoned that a significant association was unlikely at the STRPs due to relatively high mutation rates [40]. Nevertheless, if detected, it would provide supportive evidence for the association and potentially help narrow the region of interest. These markers were also examined in the Singapore cohort.

Interleukin-1 (IL-1) Gene Complex

Cytokines such as IL-1 α , as well as the respective receptors have been localized to the brain [41]. They can modify the metabolism of neurotransmitters [42]. Because IL-1 α acts as an astroglial growth factor, it may influence neurodevelopment as well as neurodegeneration [43]. Due to these diverse roles, cytokines have been suggested in the pathogenesis of schizophrenia [44]. Indeed, elevated plasma concentrations of IL-1 β have been noted among drug naïve patients with recent onset of schizophrenia [5]. However, such findings may reflect epiphenomena like sleep loss or stress, rather than genuine pathogenic mechanisms [21]. Genetic evidence may be more convincing. Therefore, interest has focused on the IL-1 gene complex on chromosome 2q13–q21. This region includes three tightly linked genes: IL-1 α , IL-1 β , and the IL-1 receptor antagonist (IL-1 RA) [45]. Restriction fragment length polymorphisms (RFLPs) at position –889 of IL-1 α , at position –511 of IL-1 β and variable number of tandem repeats (VNTRs) in the intronic sequence of IL-1RA were recently investigated among Finnish cases with schizophrenia ($n = 50$) and unrelated blood donors ($n = 400$) [20]. Though significant case-control differences in allele frequencies were not detected for any of these three polymorphisms, the cases had a significant excess of individuals homozygous for the following haplotype: IL-1 α allele 2/IL-1 β allele 1/IL-1 RA allele 1. These findings are provocative, because the IL-1 α polymorphism has functional relevance, and the IL-1 complex may be associated with ulcerative colitis as well as juvenile rheumatoid arthritis [46–48]. To test if

similar associations occur among the Chinese, both the Singapore and Guangzhou samples were examined.

MATERIALS AND METHODS

Clinical

Singapore sample. The Chinese cases and adult controls have been described earlier [38]. Briefly, the cases were male inpatients with schizophrenia (ICD10 criteria) at Woodbridge Hospital, the only psychiatric hospital in Singapore. The controls were individuals screened for a pre-employment checkup at the National University Hospital, Singapore. For all participants, ethnicity was based on self report. The sample included 171 cases and 130 controls. Informed consent was obtained from participants, in accordance with the regulations of Singapore University and the University of Pittsburgh Institutional Review Board (IRB).

Guangzhou sample. The cases were consenting inpatients with schizophrenia of Han Chinese ethnicity (DSM IV criteria). All cases were interviewed by two psychiatrists using the Structured Clinical Interview for DSM IV Axis I Disorders, Patient edition (SCID-P), [49]. The controls were unscreened unrelated adults from the same residential area as the cases. The sample included 100 cases and 99 controls. The study was approved by the Ethics Committee at Guangzhou Psychiatric Hospital and the University of Pittsburgh IRB.

Laboratory

DNA extraction. Genomic DNA was extracted from venous blood using the phenol chloroform method.

Chromosome 6p markers. In addition to HLA DQB1, five anonymous markers less than 100 kb from HLA DQB1 were analyzed. They included four short tandem repeat polymorphisms (STRPs): DQCAR2 (18 alleles), DQCAR (14 alleles), G5-1152 (15 alleles), G4-12348 (7 alleles), and G6-7571, a bi-allelic marker (Figure 1).

Genotypes at HLA DQB1 were determined using PCR amplification with sequence specific primers (SSP) [50]. The STRPs at DQCAR were typed using a PCR based assay [51, 52]. The amplified fragments were separated electrophoretically using 6% acrylamide gels and visualized using silver stain [53]. Other STRPs were analyzed using published PCR based assays [54–57]. All gel runs included as reference amplified DNA from CEPH individuals whose genotypes were known. Genotypes were read by two workers blind to the clinical status of the subject. In case of ambiguity, samples were retyped.

The marker G6-7571 was initially reported as a single strand conformational polymorphism (SSCP) [55]. To identify the sequence variation causing the SSCP, we identified four individuals with varying SSCP patterns. PCR amplified fragments from these individuals were purified using Quiagen Extraction Kits, sequenced using cycle sequencing kits (Applied Biosystems) and electrophoresed on an ABI 373 DNA Sequencer. The sequences from the variant genotypes were analyzed using multialignment sequence analysis software (CLUSTAL). We identified a T → C substitution, recognized by the restriction endonuclease MSc I. Therefore, the rest of the samples were PCR amplified, digested using MSc I, electrophoresed on 2% agarose gels and the fragments visualized with ethidium bromide.

Chromosome 2q markers. Three polymorphisms were investigated at the IL-1 gene cluster: bi-allelic markers at IL1A (-889) and IL1B (-511) and a variable number of tandem repeat marker (VNTR) at IL1RN. Published PCR based assays were employed [20, 45]. Amplified DNA fragments were visualized by electrophoresis on 2% agarose gels followed by ethidium bromide staining.

Statistical analysis. Case-control differences in allele frequencies for bi-allelic markers were compared using Chi square tests. For comparisons involving small cells, the likelihood ratio chi square statistic was used. Such comparisons are invalid for multi-allelic markers such as STRPs, due to the large numbers of cells. Therefore, the computer program CLUMP was used [58]. Using Monte Carlo simulations, it generates tables with the same marginal totals as the table with the raw data. The number of times the chi square value from the raw data exceeds the respective values from the simulated data set is counted. This provides an estimate of the significance of the raw values. When significant case-control differences were detected thus, chi square tests were used to compare frequencies of individual alleles and odds ratios computed when significant differences were detected.

RESULTS

Analysis of Chromosome 6p Markers

HLA DQB1 (Guangzhou sample). CLUMP analysis revealed a significant association at HLA DQB1 when overall allelic distributions were compared ($p < 0.0001$, Table 1). Genotypes and allele counts for each allele were also compared among cases and controls using Chi square

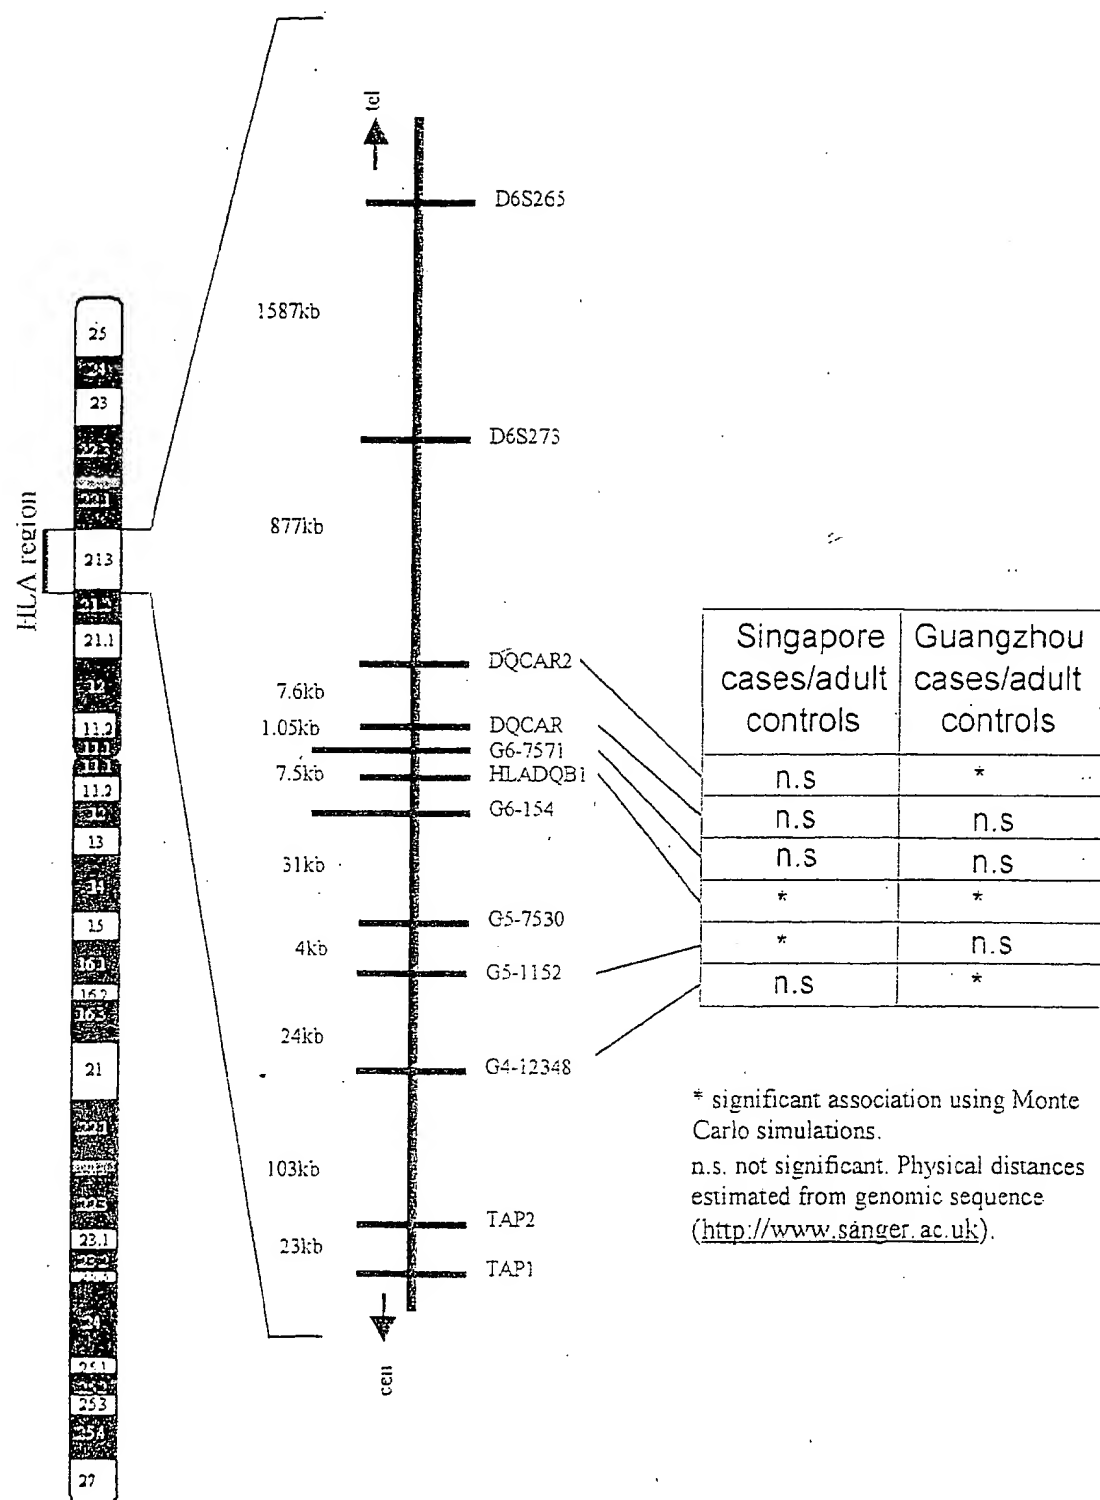

FIGURE 1 Chromosome 6p polymorphisms analyzed.

tests. Following correction for multiple comparisons, a negative association with HLA DQB1*0402 was noted ($\chi^2 = 11.5$, $p < 0.02$, 1 df; cases: 0.04 ± 0.01 , controls: 0.15 ± 0.03 , frequency \pm SD; Odds ratio, OR 0.26, 95% confidence intervals, CI 0.1, 0.6). Similarly, genotype comparisons revealed significant case control differences with respect to HLA DQB1*0402, ($\chi^2 = 12.9$, $p < 0.02$, 1df). Genotype and allele count differences were also noted at three other alleles (HLA DQB1*0301, *0302 and *0303), but did not remain significant after correction for multiple comparisons (Table 1).

Anonymous Markers Flanking HLA DQB1 (Singapore and Guangzhou Samples)

Singapore sample. In addition to the association at HLA DQB1 reported on previously, significant case-control differences were detected at one other locus. CLUMP analysis revealed significant case-control differences in overall allelic distribution of G5-1152, an STRP less than 50 kb centromeric to HLA DQB1 ($p < 0.02$; cases: $n = 154$; controls: $n = 111$). No significant associations were detected at the other markers investigated, including G6-7571 (Figure 1, Table 2).

TABLE 2 Genotypes for G6-7571 polymorphism among cases and controls. Genotype 1.1 denotes individuals homozygous for the allele 1 (T/T), 2.2 denotes allele 2 homozygous individuals (C/C) and 1.2 denotes heterozygous individuals. Apart from the Guangzhou cases, all other groups were in Hardy Weinberg equilibrium ($\chi^2 = 6.5$, $p < 0.05$, 1 d.f.).

Genotype	Guangzhou Cases (85)	Controls (77)	Singapore Cases (107)	Controls (51)
1.1 (85 bp + 179 bp)	24	14	8	5
1.2 (264 bp + 179 bp + 85 bp)	25	30	50	32
2.2 (264 bp)	36	33	49	14

TABLE 3 Genotypes for IL-1 gene cluster polymorphisms among cases and controls. Published allelic nomenclature was used (Katila *et al.* 1999). Respective allele sizes are shown in brackets.

A1/A4	0	3	0	0

Guangzhou sample. CLUMP analysis suggested significant associations in the Guangzhou sample at two markers flanking HLA DQB1: DQCAR2 and G4-12348 (Figure 1; DQCAR2: $p < 0.01$; cases: $n = 97$; controls: $n = 96$; G4-12348: $p < 0.01$; cases: $n = 92$; controls: $n = 97$).

Analysis of Chromosome 2q Markers

Guangzhou sample. No significant case-control differences were noted with respect to allele or genotypes at any of the three polymorphisms analyzed (Table 3, Figure 2). Using these genotypes, haplotypes were also estimated [59]. No significant haplotype differences were noted.

Singapore sample. No significant case-control differences were detected with respect to genotypes or allele frequencies when the IL-1 β and the IL-1RN markers were analyzed (Table 3, Figure 2).

DISCUSSION

The present study follows our earlier report of an association between schizophrenia and alleles of the HLA DQB1 gene among the Chinese [38]. We sought a replication in an independent cohort from Guangzhou, China. A significant association with HLA DQB1*0402

was detected in the Guangzhou cohort. Since associations with HLA DQB1*0602 and HLA DQB1*0303 were noted using the Singapore sample, the present report cannot be considered a replication. There are several possible reasons for the differing associations, including sample size variations, clinical heterogeneity, or genetic dissimilarities between the Singapore and Guangzhou samples.

The Guangzhou sample was smaller than the Singapore sample. The reduced power may explain why HLA DQB1*0303, one of the alleles associated in the Singapore sample failed to attain statistical significance in the Guangzhou sample following Bonferroni correction. The absence of familial samples precluded Mendelian checks for the genotypes. Therefore, uncertain genotype calls were excluded from analysis, resulting in varying sample sizes for the markers. Such variations may account for the fact that associations were observed at different markers flanking HLA DQB1 in both samples. Insofar as associations were noted at several markers, it is unlikely that exclusion of variable numbers of samples at these markers led to a systematic bias.

Apart from size, the Guangzhou sample also differed from the published Singapore sample with respect to diagnostic criteria (DSM IV criteria, Guangzhou sample versus ICD 10 criteria, Singapore sample). These samples also differed in the choice of controls. The Guangzhou

FIGURE 2 Allele frequencies for IL-1 gene cluster polymorphisms.

sample included both genders, while the Singapore sample was restricted to males.

The differing HLA associations in the Singapore and Guangzhou samples could also be due to genetic factors. One possibility is allelic heterogeneity. Though both our Chinese samples were of Han Chinese ethnicity, anthropological and genetic evidence suggests diversity within this ethnic group [60]. The possibility of an unknown primary disease susceptibility gene linked to different HLA DQB1 alleles in these two samples cannot be excluded. Such an explanation is plausible since the precise bounds of the associated region are unclear from the present study. Prior studies among Japanese samples have suggested associations with alleles of HLA DRB1, a gene in strong linkage disequilibrium with HLA DQB1 [22]. Since HLA DRB1 alleles were not examined in the present study, such associations cannot be discounted. Recent family based association analyses in a Caucasian sample also implicated NOTCH4, a gene localized to the HLA Class III region [61]. Thus, a primary association at one or more non-immune related genes is possible, as documented for hemochromatosis, another disease with significant associations in the HLA region [62].

It is also possible that the different associations in our Chinese samples reflect "spurious associations." Population stratification resulting from differing rates of admixture among cases and controls can lead to such artifacts. This possibility needs to be addressed using family based samples [63]. The familial samples may also be more informative than the presently available unrelated individuals for identification of disease associated haplotypes.

The analysis using the Singapore sample should be considered an extension and not an independent replication of our earlier report, because the cases and adult controls reported on here were used to detect the initial association. Nevertheless, they lend support to the prior reported associations in the HLA class II region. In the present analyses, suggestive associations were noted at an additional marker among the cases and screened adult controls. This reduces the likelihood of chance differences due to genotyping errors. In contrast, associations were not detectable at the same markers flanking HLA DQB1 in the Guangzhou sample. The reasons for these inconsistencies are unclear and may be related to the differences outlined above. The associations at these loci in close physical proximity are most likely to be due to the well known linkage disequilibrium in the HLA region [64]. It was not possible to evaluate recombinants in the present study due to the absence of parental information, even though others have reported recombinations in the HLA class II region [54, 65-67].

We also examined possible associations with IL-1 polymorphisms in our present analyses, following a re-

ported haplotype based association in a Finnish sample [20]. Plausible evidence for an association was not revealed in either sample. The discrepancy between our report and the earlier study may stem from differences in the ethnic groups.

In conclusion, the present study provides suggestive, but not conclusive evidence for, an association between schizophrenia and markers on chromosome 6p21 among two independent Chinese samples. If they represent true genetic associations, the findings are unlikely to explain more than a fraction of the genetic risk for schizophrenia. Furthermore, details of family history were unavailable for either sample. Therefore, it is not known if the associations are more evident among familial cases. Conclusive evidence for an association with IL-1 polymorphisms was not present in either sample. Further studies are in progress.
